Keywords: entropy, randomness, spike train, variability

Abstract

Fast information transfer in neuronal systems rests on series of action potentials, the spike trains, conducted along axons. Methods that compare spike trains are crucial for characterizing different neuronal coding schemes. In this paper we review recent results on the notion of spiking randomness, and discuss its properties with respect to the rate and temporal coding schemes. This method is compared with other widely used characteristics of spiking activity, namely the variability of interspike intervals, and it is shown that randomness and variability provide two distinct views. We demonstrate that estimation of spiking randomness from simulated and experimental data is capable of capturing characteristics that would otherwise be difficult to obtain with conventional methods.

Introduction

Neurons communicate via chemical and electrical synapses, in a process known as synaptic transmission. The crucial event that triggers synaptic transmission is the action potential (or spike), a pulse of electrical discharge that travels along the axon excitable membrane. The shapes and durations of individual spikes generated by a given neuron are very similar, therefore it is generally assumed that the form of the action potential is not important in information transmission. The series of action potentials in time (spike trains) can be recorded by placing an electrode close to or inside the soma or axon of a neuron. Because individual spikes in a spike train are usually well separated, the whole spike train can be described as a series of all-or-none point events in time (Gerstner & Kistler, 2002). The lengths of interspike intervals (ISIs) between two successive spikes in a spike train often vary, apparently randomly, both within and across trials (Shadlen & Newsome, 1998; Gerstner & Kistler, 2002; Stein et al., 2005). In order to describe and analyse neuronal firing, statistical methods and methods of probability theory and stochastic point processes have been widely applied (Cox & Lewis, 1966; Moore et al., 1966; Tuckwell, 1988; Kass et al., 2005).

One of the most fundamental questions in neuroscience has been the problem of neuronal coding, i.e. the way information about stimuli is represented in spike trains (Perkel & Bullock, 1968; Softky, 1995; Strong et al., 1998). To answer this question, methods to compare different spike trains are needed first (Rieke et al., 1997; Victor & Purpura, 1997; Buracas & Albright, 1999; Paninski, 2003; Bhumbra et al., 2004; Nemenman et al., 2004).

In the rate coding scheme information sent along the axon is encoded in the number of spikes per observation time window (the firing rate; Adrian, 1928). In most sensory systems, the firing rate increases, generally non-linearly, with increasing stimulus intensity (Kandel et al., 1991). Any information possibly encoded in the temporal structure of the spike train is ignored. Consequently, rate coding is inefficient but highly robust with respect to the ISI ‘noise’ (Stein et al., 2005). The question whether the temporal structure of ISIs is due to unavoidable fluctuations in spike generation or whether it represents an informative part of the neuronal signal is not yet fully resolved (Shadlen & Newsome, 1994; Gerstner & Kistler, 2002; Stein et al., 2005) and leads to the idea of temporal coding.

Temporal codes employ those features of the spiking activity that cannot be described by the firing rate. For example, time to first spike after the stimulus onset, characteristics based on the second and higher statistical moments of the ISI probability distribution, or precisely timed groups of spikes (temporal patterns) are candidates for temporal codes (Rieke et al., 1997; Buracas & Albright, 1999; Gerstner & Kistler, 2002). The possibility of information transmission by changes in ISIs serial correlation has been reported in crayfish interneurons (Wiersma & Adams, 1950; Sugano & Tsukada, 1978). For a classic overview of temporal coding, see Perkel & Bullock (1968), for a more recent discussion, see Abeles (1994), Rieke et al. (1997), Shadlen & Newsome (1994); Stein et al. (2005) and Theunissen & Miller (1995). It is worth noting that both rate and temporal coding schemes generally depend on the length of the observation window, and therefore their precise separation may not be possible in general (Gerstner & Kistler, 2002). However, if the firing is stationary the rate does not depend on the observation window length, and thus both coding schemes are well separated.

While the description of neuronal activity from the rate coding point of view is relatively straightforward, the temporal coding allows an infinite number of possibilities. Spike trains that are equivalent from the rate coding perspective may turn out to be different under various measures of their temporal structure. The purpose of this review is to describe a measure of randomness of the neuronal activity. We discuss properties of this measure with respect to rate and temporal coding schemes, and its application to experimental data. We show that spiking randomness is capable of capturing characteristics that would
otherwise be difficult to obtain with conventional methods. The notion of randomness is very different from that of variability, even though these terms are sometimes interchanged. Furthermore, because the definition of randomness is based on the concept of entropy (Shannon & Weaver, 1998), the relation with other information-theoretic quantities can be established.

**Probabilistic description of neuronal activity**

Spike train consists of times of spike occurrences \( \tau_0, \tau_1, \ldots, \tau_n \). For the purpose of further analysis it is advantageous to describe such spike train equivalently by a set of \( n \) ISIs \( t_i = \tau_i - \tau_{i-1}, \) \( i = 1, \ldots, n \). Arguably the most important characteristics calculated from \( t_i \) is the estimate \( \bar{t} \) of the mean ISI,

\[
\bar{t} = \frac{1}{n} \sum_{i=1}^{n} t_i.
\]

(1)

Because \( \sum_{i=1}^{n} t_i = \tau_n - \tau_0 \), the average \( \bar{t} \) is computed without recourse to particular interval lengths and thus presents the lowest level of ISI analysis (Moore et al., 1966). Other common parameters, coefficient of variation and standard deviation of ISIs, require all measurements, \( t_i \), and both rely on the estimate \( s^2 \) of the ISI variance,

\[
s^2 = \frac{1}{n-1} \sum_{i=1}^{n} (t_i - \bar{t})^2.
\]

(2)

However, \( \bar{t} \) and \( s^2 \) are meaningful only if the spiking activity is stationary, i.e. if the major probability characteristics of the firing are invariant in time (Cox & Lewis, 1966; Landolt & Correia, 1978). Stationary neuronal firing is typically observed in the spontaneous activity, or under constant stimulus conditions (Moore et al., 1966; Tuckwell, 1988; Gerstner & Kistler, 2002).

The probabilistic description of the spiking results from the fact that the positions of spikes cannot be predicted deterministically, only the probability that a spike occurs can be given (Gerstner & Kistler, 2002). By far the most common probabilistic descriptor is the ISI probability density function \( f(t) \), where \( f(t) \, dt \) is the probability that spike occurs in an interval \([t, t + dt]\) (Moore et al., 1966). The probability density function is usually estimated from the data by means of histograms.

There are several functions completely equivalent to \( f(t) \) that characterize the spiking activity (Cox & Lewis, 1966; Landolt & Correia, 1978). The cumulative distribution function \( F(t) \),

\[
F(t) = \int_{0}^{t} f(z)dz,
\]

(3)

gives the probability that the ISI will have a length not greater than \( t \). \( F(t) \) is easily estimated from data by means of empirical cumulative distribution function (Cox & Lewis, 1966; Duchamp-Viret et al., 2005), which serves as a basis for some differential entropy estimators (see Appendix B). The final probability descriptor we mention is the hazard rate \( r(t) \),

\[
r(t) = \frac{f(t)}{1 - F(t)}.
\]

(4)

The hazard rate determines the probability \( r(t) \, dt \) of spike occurring in a time interval \([t, t + dt]\) under the condition that there was no firing in \([0, t] \). The hazard rate characterizes the ‘imminency’ of spiking (Tuckwell, 1988), and it has been traditionally employed in neuronal data analysis (Adrian et al., 1964; Poggio & Viernstein, 1964; Moore et al., 1966) to provide a different point of view from \( f(t) \) and \( F(t) \).

The mentioned descriptors, \( f(t), F(T) \) and \( r(t) \), do not depend on the ordering of ISIs, i.e. they completely describe the firing when ISIs are mutually independent realizations of a positive random variable \( T \), with mean ISI \( E(T) \) and variance \( \text{Var}(T) \) estimated by Eqs (1) and (2).

Such firing is called the renewal process of ISIs (Cox & Lewis, 1966; Gerstner & Kistler, 2002). The plausibility of renewal models under steady-state stimulus conditions is supported by the observation that after a spike is emitted, the membrane potential of the cell returns to its (approximately) constant resting value (Stein, 1967; Landolt & Correia, 1978; Tuckwell, 1988; Gerstner & Kistler, 2002). Sometimes, however, there might be a dependency structure between the observed ISIs (Longtin & Racicot, 1997; Lansky & Rodríguez, 1999; Sakai et al., 1999; Ratnam & Nelson, 2000; Chacron et al., 2001; Lindner, 2004). The dependence may arise, for example, due to incomplete resetting of the membrane potential after the spike is emitted, which is experimentally observed especially in the distal parts of the neuron (Abeles, 1982). Such a type of neuronal firing is not a renewal process, although the ISI probability distribution is invariant in time (due to the stationarity of spiking). Consequently, the mean ISI is constant in time, and therefore \( E(T) \) carries all the information from the rate coding point of view, as \( E(T) \) is inversely proportional to the (mean) firing rate (Moore et al., 1966; Gerstner & Kistler, 2002). Basic observation reveals, however, that even if the firing rates are the same, the resulting spike trains can have very different appearances (Fig. 1). See Appendix C for the description of models employed in the figure.

**Spike variability**

One of the most frequently used characteristics of renewal neuronal firing is the ISI variability. The variability may be measured simply using the ISI variance, \( \text{Var}(T) \), but variance depends on the mean ISI. Usually, it is required to characterize the spike train differences from the temporal coding point of view, in other words to describe properties that are distinct from the mean ISI. To achieve this the ISI lengths are rate-normalized, i.e. individual ISIs are divided by the mean ISI,

\[
\theta = \frac{T}{E(T)},
\]

(5)

so we obtain a new dimensionless random variable \( \theta \) with mean \( E(\theta) = 1 \). Variance of \( \theta \) is equal to the coefficient of variation of the original random variable \( T \), \( \text{Var}(\theta) = C_V \), where

\[
C_V = \frac{\sqrt{\text{Var}(T)}}{E(T)}.
\]

(6)

The main advantage of \( C_V \) as a measure of spiking variability (compared with variance) is that \( C_V \) is dimensionless and its value does not depend on the choice of units of ISIs (e.g. seconds or milliseconds), and thus ISI probability distributions with different means can be compared meaningfully (Softky & Koch, 1993). Furthermore, the \( C_V \) of ISIs is related to the variability coding hypothesis (Perkel & Bullock, 1968). The coding characterized by \( C_V \) has been hypothesized to transmit information about light intensity in adapted cells of the horseshoe crab (Ratliff et al., 1968). Changes in the level of bursting activity, characterized by values \( C_V > 1 \), are
Fig. 1. Examples of different simulated spike trains. The mean ISI is $E(T) = 1$ s in all cases, thus the spike trains (a–h) are equivalent in the rate coding scheme. The temporal coding scheme must be used to classify the apparent differences. The ISI variability (measured by the coefficient of variation, $C_V$) is not sufficient for (b–e). The ISIs described by the exponential probability distribution (b) have many different lengths (i.e. they are 'variable'), but the same variability is achieved for a regular spiking disturbed by appropriately long pauses (c). Activity described by the Pareto distribution (d) has the same variability ($C_V = 1$), though it lacks short ISIs. Finally, (e) contains the same individual ISIs as (b) but ordered in a particular way (Markov chain, first-order serial correlation $\rho = 0.9$). The measure that describes the differences is randomness, $\eta$, defined as the ‘choice’ of possible ISIs when reconstructing the spike train ‘spike by spike’. Spike trains (f–h) were simulated using the same random seed to make the visual comparison easier. The differences in randomness between cases (f) and (g) with equal $C_V$ are not as apparent as in (b–e). The same level of randomness, in (g) and (h), is reached with different variability and results in different spike trains. Bursting activity (h) is more variable than the exponential case (a), though its randomness is lower.
reported to be the proper code for edge detection in certain units of the visual cortex (Burns & Pritchard, 1964) and also in hippocampal place cells (Fenton et al., 2002). The variability of ISIs generated by the leaky integrate-and-fire model (Gerstner & Kistler, 2002; Burkitt, 2006) was recently a topic for a very extensive discussion initiated by Sofyky & Koch (1993).

Nevertheless, \( E(T) \) and \( C_V \) are not sufficient to describe all possible differences between spike trains (Fig. 1b–e, where \( E(T) = 1 \) s and \( C_V = 1 \)). The spike trains described by the renewal processes of equal variability may have ISI probability distributions that differ in higher than second statistical moments. Additionally, \( C_V \) does not account for statistical dependency between ISIs (by definition), and thus spike trains with the same marginal probability distributions of ISIs have the same variability.

Instead of employing characteristics based on higher statistical moments of the probability distributions involved and serial correlation coefficients of the ISIs, we propose to measure the randomness of the spiking activity. Spiking randomness accounts automatically for differences in both marginal probability distributions and serial dependence of ISIs.

### Spiking randomness

The randomness of spiking can be defined as the measure of ‘choice’ of different ISI lengths that appear in the spike train and the measure of ‘freedom’ in their serial ordering. A bigger choice of ISIs and more freedom in their ordering results, intuitively, in greater randomness of spiking. We first overview the concept of entropy (Shannon & Weaver, 1998), on which the measure of spiking randomness is based.

For a discrete random variable \( X \) with the set of possible states \( \{x_1, x_2, \ldots, x_n\} \) and the corresponding probability mass function \( p_i = \text{Prob}(X = x_i) \), the entropy \( H(X) \) is defined as (Shannon & Weaver, 1998)

\[
H(X) = -\sum_{i=1}^{n} p_i \ln p_i.
\]

The entropy \( H(X) \) is positive or equal to zero with equality if only one option is possible (no randomness). Maximum randomness [maximum \( H(X) \)] is reached when all \( p_i \)'s are the same. If the logarithm base in Eq. (7) is 2, \( H(X) \) can be interpreted as the average length in bits of the shortest description of \( X \) (Cover & Thomas, 1991). The entropy is a unique measure of randomness satisfying a set of intuitive conditions (Shannon & Weaver, 1998; Jaynes & Bretthorst, 2003); however, it is applicable to discrete systems only.

The extension of Eq. (7) for continuous probability distributions is impossible because the value of \( H(X) \) diverges (Cover & Thomas, 1991). Therefore, the differential entropy \( h(T) \) of the ISI probability density function \( f(t) \) is defined as

\[
h(T) = -\int_{0}^{\infty} f(t) \ln f(t) dt.
\]

Differential entropy \( h(T) \) does not have all the properties and intuitive interpretation of the entropy \( H(X) \). The value of \( h(t) \) changes with coordinate transforms, e.g. it depends on the time units of ISIs. The probability density function \( f(t) \) has a physical dimension (it is a derivative of probability with respect to time), therefore \( h(T) \) has the dimension of its logarithm, e.g. logarithm of a millisecond. These facts show that the differential entropy cannot be used to quantify the randomness of spiking activity. To overcome this problem, a discretization method has been adopted in the literature (Rieke et al., 1997; Strong et al., 1998), which converts the task back to Eq. (7); however, the results depend on the discretization factor (Chacron et al., 2001).

Here we proceed in a different way, avoiding the discretization. We want the randomness to characterize the spike train differences from the temporal coding point of view, in a similar way to \( C_V \). Thus, Eq. (5) is employed to rate-normalize the ISI lengths, and the spiking randomness \( \eta \) is defined as the differential entropy of the random variable \( \theta \). The following relation holds (Kostal et al., 2007)

\[
\eta = h(T) - \ln E(T).
\]

Before discussing the properties of \( \eta \) we mention another approach to defining randomness. The exponential probability density function, \( f_{\text{exp}}(t) \), is given as

\[
f_{\text{exp}}(t) = \lambda e^{-\lambda t},
\]

where \( \lambda > 0 \) is the inverse of its mean, \( \lambda = 1/E(T) \). An important property of \( f_{\text{exp}}(t) \) is that it achieves maximum differential entropy among all ISI probability distributions with the same mean ISI (Cover & Thomas, 1991). The exponential model \( f_{\text{exp}}(t) \) represents the ‘zero point’ on the differential entropy scale for all ISI probability density functions with the same means. Kullback–Leibler (KL) distance \( D(f, f_{\text{exp}}) \), given by formula (Cover & Thomas, 1991)

\[
D(f, f_{\text{exp}}) = \int_{0}^{\infty} f(t) \ln \frac{f(t)}{f_{\text{exp}}(t)} dt
\]

measures the deviation between probability density functions \( f(t) \) and \( f_{\text{exp}}(t) \). Therefore, \( D(f, f_{\text{exp}}) \) can be used to quantify the randomness of the probability density function \( f(t) \), if \( f(t) \) has the same mean as \( f_{\text{exp}}(t) \) (Kostal & Lansky, 2006c). It can be shown that \( \eta \) is related to \( D(f, f_{\text{exp}}) \) by a simple formula (Kostal et al., 2007)

\[
\eta = 1 - D(f, f_{\text{exp}})
\]

and thus both proposed measures of randomness, \( \eta \) and \( D(f, f_{\text{exp}}) \), are equivalent in their properties because their values differ only in a sign and a constant. Equation (9) can be naturally extended to account for non-renewal spiking activity (Kostal & Lansky, 2006a), see Appendix A.

Finally, by employing the hazard rate from Eq. (4), we provide an independent justification for maximum randomness of the exponential distribution. Intuitively, the most random firing makes the time to the first spike (since the last observed spike) most unpredictable. In other words, the probability of first spike occurring in \( [t, t + dt] \) must be independent of the elapsed time \( t \) and, consequently, the hazard rate must be constant. (Any dependence of \( r(t) \) on \( t \) would lead to increased predictability of firing due to more probable first spike occurrence after certain elapsed times.) The only ISI probability distribution with constant \( r(t) \) is the exponential distribution defined in Eq. (10), then \( r(t) = 1/\lambda \). Even though the randomness \( \eta \) can be determined from \( r(t) \) (and not vice versa), we see two main advantages of \( \eta \) over \( r(t) \) as a measure of randomness. First, \( r(t) \) is a function not a number (contrary to \( \eta \)), and therefore comparison of randomness of
different ISI distributions by means of $r(t)$ is difficult (Kostal & Lansky, 2006c). Second, while $\eta$ in its general form accounts also for non-renewal spiking activity, $r(t)$ is used only in the renewal case (Moore et al., 1966).

**Properties of spiking randomness**

Here we summarize the basic properties of the spiking randomness $\eta$, and compare it with the properties of variability as measured by the coefficient of variation $C_V$.

- Due to rate-normalization of the ISI probability distribution, the randomness $\eta$ is a dimensionless quantity and does not depend on coordinate transformations (Kostal et al., 2007). Consequenly, $\eta$ allows to compare different stationary spiking activities in the same way as $C_V$.

- Maximum spiking randomness is generated only by the renewal process with exponential probability distribution of ISIs (Poisson process; Fig. 1a). Substituting Eq. (10) into Eq. (9) gives $\eta = 1$. Any non-renewal spiking activity with exponential marginal probability distribution of ISIs must have $\eta < 1$, as less freedom in serial ordering of ISIs results in smaller randomness (Kostal & Lansky, 2006a).

- Coincidentally, both $\eta = 1$ and $C_V = 1$ for exponential distribution. Many non-exponential probability distributions can have $C_V \approx 1$, but their randomness is always $\eta < 1$. The equality $\eta = 1$ completely characterizes the exponential distribution of ISIs.

- Equally variable spike trains may differ in their randomness. However, the same spiking randomness may be achieved with different spiking variabilities (Fig. 1g and h). Thus, randomness provides an alternative rather than superior characteristic of neuronal firing compared with variability (Kostal et al., 2007).

- $C_V$ is limited from below by $C_V = 0$ (regular spiking; Fig. 1a), but there is no maximum spiking variability. Values $C_V > 1$ are characteristic of bursting activity (Fig. 1h). On the other hand, there is no unique minimal randomness probability distribution, because $\eta = -8$ for any discrete random variable (Fig. 1a and c). However, discrete probability distributions are not valid models of spiking activity (SI 'noise' is always present), and the fact that $\eta$ may not be finite is of little practical consequence (Kostal & Lansky, 2006a).

- Spiking randomness is an information-theoretic measure, related to entropy and KL distance. The strength of information-theoretic measures lies in their ability to reveal non-linear dependencies (Cover & Thomas, 1991; Yamada et al., 1993; Rieke et al., 1997). Recently, KL distance has been used in the field of neuronal coding from the classification theory point of view (Johnson et al., 2001) and as a predictor of purely rate coding models (Johnson & Glantz, 2004). Renormalized entropy (a special case of KL distance) has been shown to provide additional information over traditional tools in electroencephalographic (EEG) record analysis (Kopitzki et al., 1998; Quiroga et al., 2000; Thakor & Tong, 2004).

**Results on model spiking activity**

Probabilistic models of stationary spiking activity may be divided into two categories: statistical and biophysical. The statistical models are described by probability density functions that are simple enough to manipulate and adequately describe experimentally observed data, but no other connection with neurophysiological reality is required. The biophysical models, on the other hand, result from attempts to describe the behaviour of real neurons at different levels of abstraction (Tuckwell, 1988; Gerstner & Kistler, 2002). However, mathematical expressions for biophysical models are rarely given in a closed form and one has to rely on numerical approximations.

The analysis of several statistical and biophysical renewal process models was performed in Kostal & Lansky (2006b,c) and Kostal et al., (2007). Here we present an overview of the main results. The statistical models are represented by gamma and lognormal ISI probability distributions, both are commonly used for experimental data description (Levine, 1991; Mack, 1992; Rospars et al., 1994; McKeegan, 2002; Duchamp-Viret et al., 2005). The inverse Gaussian distribution (Chhikara & Folks, 1989) results from a simple point stochastic neuronal model (perfect integrator) where the approach of the membrane potential towards the threshold is described by the Wiener process with a positive drift (Berger et al., 1990; Levine, 1991). The inclusion of leakage current into this model results in the more realistic diffusion leaky IF model (Tuckwell, 1988; Burkitt, 2006), where the membrane potential evolution is described by the Ornstein–Uhlenbeck process. The parameters of the leaky IF model determine two firing regimes, depending on the ratio $\xi = S/(\mu t)$ of the threshold membrane potential $S$ to the neuronal input $\mu$ and membrane time constant $\tau$ (Burkitt, 2006; Kostal et al., 2007). The subthreshold regime is characterized by $\xi > 1$, supra-threshold by $\xi < 1$. The gamma, lognormal and inverse Gaussian distributions are completely characterized by $E(T)$ and $C_V$, and therefore it is possible to calculate a unique value of $\eta$ for each value of $C_V$ [note that $\eta$ is independent of $E(T)$]. A similar calculation is possible for the leaky IF model once $\mu$, $\tau$ and $S$ are known (determining the supra- or subthreshold regimes), because the amount of input ‘noise’ $\sigma^2$ controls the actual value of $C_V$ (Kostal et al., 2007). The following inference can be made based on Fig. 2, where the randomness of each model is plotted against the corresponding variability.

- The randomness–variability curves of the investigated models are often U-shaped, with high randomness values distributed around $C_V = 1$. The notable exceptions are the subthreshold regime of the leaky IF model and the statistical Pareto model (not included; Kostal & Lansky, 2006a).
• While small variability generally implies low randomness, high variability in the firing may result in both low as well as high randomness.

• It is well known that the lognormal, inverse Gaussian and leaky IF supra-threshold ISI distributions never become exponential, but in addition their maximum randomness (minimal KL distance from the exponential model) is not located at $CV = 1$.

• The behaviour of the leaky IF model in the supra-threshold regime is comparable to the perfect integrator (inverse Gaussian model). In the subthreshold regime, the effect of coherence resonance (Lindner et al., 2002) is demonstrated by local decrease of $CV$ for $\eta \approx 0.96$. However, there is no corresponding local decrease in spiking randomness, i.e. the coherence resonance for certain (high) values of $\zeta$ is observable in $CV$ but not in $\eta$. Though it is known that the degree of coherence resonance depends on the measure employed (Lindner et al., 2004), the apparent disappearance of the effect on the $\eta$ scale raises the question of what is the proper measure of ISI coherence (Kostal et al., 2007).

Several statistical models of non-renewal spiking activity described by first-order Markov chains (Cox & Lewis, 1966) were examined in Kostal & Lansky (2006a). Markov structure in experimental data is reported in the literature (Ratnam & Nelson, 2000), and even the first-order case makes the existence of certain (short) sequences of ISIs more probable than others (basic temporal pattern formation; Kostal & Lansky, 2006a). Although the examined models were not used in data analysis previously, the results show that the serial correlation coefficient (Cox & Lewis, 1966) is a weak indicator of the true ISI serial dependence. For example, the Lawrance and Lewis model with exponential marginal probability distribution of ISIs (Lawrance & Lewis, 1977) can achieve either randomness $\eta = 0.97$ or $\eta = 0.82$ for the same value of first-order serial correlation $\rho = 0.17$. It follows that randomness $\eta$ or mutual information between ISIs (Cover & Thomas, 1991) should be employed when deciding on renewal or non-renewal character of experimental data. However, estimation of these information-theoretic quantities requires large amounts of data, which are usually not available in experimental recordings. Finally, we note that the maximum order of non-zero serial correlation coefficient does not coincide with the dimension of the joint probability density function describing the activity. For example, the first-order moving average process is non-renewal, with all second- and higher-order serial correlations equal to zero. However, joint probability density function of two adjacent ISIs does not describe such process, as the Markov property, $\text{Prob}\{T_n = t_{n}\,|\,T_{n-1} = t_{n-1}\}$, $\ldots$, $T_1 = t_1 = \text{Prob}\{T_n = t_{n}\,|\,T_{n-1} = t_{n-1}\}$ (Cox & Lewis, 1966), does not hold in this case.

### Results on simulated and experimental data

Here we provide an example with practical consequences, showing that estimates of randomness from two spike trains may differ significantly, although their appearance is very similar (Fig. 1f and g) and their histograms are almost identical.

Bursting neuronal activity consists of runs of short ISIs (bursts) interspersed among comparatively longer ISIs. Bursting is usually characterized by $CV > 1$ and it is often reported in experimental data analysis. (Rospars et al., 1994; Bhumbra et al., 2004; Duchamp-Viret et al., 2005). The bursting activity of neurons is usually described by a mixture of two distributions, one for interburst ISIs and the other for intraburst ISIs. A common model of bursting activity is given by a probability density function of the mixture of two exponential (ME) distributions (Smith & Smith, 1965; Tuckwell, 1988)

$$f(t) = pae^{-at} + (1 - p)be^{-bt},$$  \hspace{1cm} (13)

where $p \in (0, 1)$ and $a > 0$, $b > 0$, $a \neq b$. The parameters $a$, $b$ and $p$ are independent and, consequently, a whole range of different randomness values can be achieved for a fixed mean ISI and $CV > 1$ (Kostal & Lansky, 2006b). We compare two simulated spike trains with $E(T) = 1$ s, $CV = 1.1$: the first generated by the gamma model (Fig. 1f) and the second generated by the ME distribution (Fig. 1g). The theoretical value of $\eta$ for the gamma model in this case is $\eta = 0.99$. The parameters in Eq. (13) were set so that $\eta = 0.80$ for the ME model. Figure 2 shows that the randomness of the ME distribution with variability $CV = 1.1$ is the lowest of the considered models with the same $CV$. The histograms of ISIs constructed from $n = 200$ spikes are, however, hardly distinguishable due to the striking similarity of spike trains in Fig. 1f and g. The estimated $CV$ values are (mean ± standard deviation): $\hat{CV} = 1.1 ± 0.06$ (gamma) and $\hat{CV} = 1.104 ± 0.05$ (ME). The estimates of randomness, $\eta$ according to Eq. (B1) (see Appendix B) with $\phi_{\text{bias}} = 0$ and $m = 14$, averaged over several runs give $\hat{\eta} = 0.91 ± 0.05$ (gamma) and $\hat{\eta} = 0.80 ± 0.05$ (gamma).

![Fig. 3. Comparison of the mixture of exponentials (ME) and gamma models with parameters $E(T) = 1$ s and $CV = 1$. The exponential model with $E(T) = 1$ s is also shown. Probability density functions (a) of ME and gamma models are almost identical for times greater than 0.5 s. However, the calculated spiking randomness $\eta$ differs significantly (Fig. 2), which is supported independently by comparing the hazard rates (b) of ME and gamma models. The gamma model approaches the constant hazard rate quickly, and therefore its spiking activity is more random than that described by the ME model with monotonously decreasing hazard rate.](image-url)
The error of estimation is acceptable, because even for 200 spikes the Vasickev’s estimator clearly marks the difference in spiking randomness. Theoretical probability density functions of the exponential, gamma and ME models (Fig. 3a) differ for very short ISIs; however, histograms with wide-enough bins hide this difference. A visual comparison of hazard rates, however, provides an independent proof that the spiking randomness of the ME model is indeed different from both the exponential and gamma model (Fig. 3b). The hazard rate of the gamma model rapidly approaches the constant value and thus confirms the small deviation in randomness from the exponential distribution, contrary to the ME distribution, which has a monotonously decreasing hazard rate. We conclude that even though conventional analysis of two spike trains reveals no difference, the spike trains may still differ in their randomness and the difference is tractable even with a limited amount of data. Values $\eta = 0.99$ and $\eta = 0.80$ may also characterize visually different spike trains. This is confirmed by comparing Fig. 1f and h with $\eta = 0.8$ but different levels of variability. The bursting activity described by the inverse Gaussian model contains more of both longer and shorter ISIs than the less variable gamma model.

Duchamp-Viret et al. (2005) estimated the randomness from the spontaneous activity recordings performed on olfactory receptor neurons of freely breathing and tracheotomized rats. The recordings were obtained under steady-state conditions, and it was shown that in the majority of cases the firing can be considered renewal. It was demonstrated that the spontaneous activity is less variable but more random in the case of tracheotomized animals than in those freely breathing. This effect is further enhanced if $\eta$ is adjusted for different spiking rates by considering instead the ratio $\eta/E(T)$, i.e. the ‘amount’ of randomness per time unit (Kostal & Lansky, 2006a).

Concluding remarks

Comparison of neuronal spiking activity under different conditions plays a key role in resolving the question of neuronal coding. The spiking activity of a neuron is usually not deterministic, therefore ISI is described by means of probability distributions. We proposed an information-theoretic measure of spiking randomness, $\eta$, which can be related to the differential entropy or KL distance from the maximum entropy distribution. Conceptually, the spiking randomness can be best compared with the more often used ISI variability measured by the coefficient of variation, $C_V$. However, the properties of randomness and variability are different. Namely, small variability generally implies low randomness, but high variability of firing may not result in high level of randomness. Simultaneously, the same level of randomness can be reached by different values of variability, depending on the probabilistic model of the spiking.

Appendix A: randomness of non-renewal firing

In the stationary, but non-renewal, spiking activity, the successive ISIs are realizations of identical, statistically dependent random variables \( \{ T_n \} \), and the activity is fully described by the joint probability density function \( f(t_1, t_2, \ldots) \) of ISIs. For the mean ISI, \( E(T) \), this holds \( E(T) = E(T_1) \) (Cox & Lewis, 1966). The appropriate generalization of differential entropy \( h(T) \) is given by the differential entropy rate \( h(f) \) (Cover & Thomas, 1991).

\[
\tilde{h}(f) = -\lim_{n \to \infty} \frac{1}{n} \sum_{t_n=1}^{\infty} \int_0^{\infty} f(t_1, \ldots, t_n) \ln f(t_1, \ldots, t_n) dt_1 \cdots dt_n. \quad (A1)
\]

Equation (A1) provides the general form of differential entropy rate, which can be significantly simplified for many cases of interest. For example, neuronal firing that is described by the first-order Markov chain (example in Fig. 1E) is fully characterized by the joint probability density function \( f(t_1, t_2) \) of two adjacent ISIs (Cover & Thomas, 1991). Equation (A1) then reads

\[
\tilde{h}(f) = -\int_0^\infty \int_0^\infty f(t_1, t_2) \ln f(t_1|t_2) dt_1 dt_2. \quad (A2)
\]

where \( f(t_2|t_1) = f(t_1, t_2)/f(t_1) \) is the conditional probability density function (Cox & Lewis, 1966).

The joint probability density function \( f(t_1, t_2, \ldots) \) describes also a general, non-stationary neuronal activity. By observing the first \( n \) spikes (from the stimulus onset) over many trials we may estimate the \( n \)-dimensional probability density function \( f(t_1, \ldots, t_n) \) that governs the immediate response of a neuron (or a population of neurons). Equation (A1) holds without the limit (for a finite \( n \)), and we may formally put \( \mu = \frac{1}{n} \sum_{i=1}^{n} E(T_i) \) instead of \( E(T) \). The randomness of any activity may be calculated according to Eq. (9); however, due to non-stationarity the interpretation of \( \eta \) with respect to the rate coding scheme becomes unclear.
Appendix B: estimation of spiking randomness from data

The definition of randomness in Eq. (9) depends on the differential entropy. The problem of differential entropy from data estimation is well exploited in literature, see e.g. Beirlant et al. (1997) and Tsybakov & van der Meulen (1994) for an overview of available techniques. It is preferable to avoid estimations based on data binning (histograms), because discretization affects the results greatly. The support of ISI distributions is always positive, which makes the application of kernel estimators problematic.

If the neuronal firing is described by the renewal process, our experience shows that the simple and well-researched Vasicek’s estimator (Vasicek, 1976) gives good results on a wide range of data (Ebrahimi et al., 1992; Esteban et al., 2001; Miller & Fisher, 2003). The Vasicek’s estimator is based on the empirical cumulative distribution function. Given the n ranked ISIs \( \{t_{(1)} < t_{(2)} < \ldots < t_{(n)}\} \), the Vasicek’s estimator \( \hat{h} \) of differential entropy reads

\[
\hat{h} = \frac{1}{n} \sum_{i=1}^{n} \ln \frac{n}{2m} (t_{(i+m)} - t_{(i-m)}) + \varphi_{\text{bias}}. \tag{B1}
\]

The positive integer parameter \( m < n/2 \) is set prior to computation, and the two following conditions hold: \( t_{(i+m)} = t_{(i)} \) for \( (i-m) < 1 \) and \( x_{(i+m)} = x_{(i)} \) for \( (i+m) > n \). The particular values of \( m \) corresponding to various values of \( n \) were determined by Ebrahimi et al. (1992). The bias-correcting factor is

\[
\varphi_{\text{bias}} = \ln \frac{2m}{n} - \frac{1}{2} \ln \left[ 1 - \frac{2m}{n} \right] + \frac{1}{2} \ln \left( 1 + \frac{2m}{n} \right), \tag{B2}
\]

Where \( \varphi(z) = \ln \Gamma(z) \) is the digamma function (Abramowitz & Stegun, 1965). Our experience with simulated data shows that for sample sizes \( n \approx 500 \) the error of estimation is relatively small (Kostal & Lansky, 2006b), the positive bias with respect to true values is not important for small samples (Ebrahimi et al., 1992; Esteban et al., 2001), and the value of \( m \) may be approximated by an integer closest to \( \sqrt{n} \). The disadvantage of Vasicek’s estimator is that it cannot be easily extended to non-renewal processes.

Non-renewal sustained neuronal activity is described by multidimensional joint probability distributions, and so more elaborate techniques have to be employed in differential entropy estimation. One popular approach (Victor, 2002; Kraskov et al., 2004) is realized by the Kozachenko–Leonenko binless estimator (Kozachenko & Leonenko, 1987), which is asymptotically unbiased and consistent, but the dimension of the problem must be known beforehand, and the underlying probability density function must be continuous. If the spiking is described by a \( d \)-dimensional probability density function, each vector \( \{t_0, t_1, \ldots, t_{d-1}+d\} \) of consequent ISIs represents a point in a \( d \)-dimensional space. If the observed spike train consists of \( N \) ISIs, then the total \( n = N - d + 1 \) of such points may be obtained (if the firing is stationary). The estimate \( \hat{h} \) then reads

\[
\hat{h} = \frac{d}{n} \sum_{i=1}^{n} \ln \lambda_i + \ln \left[ \frac{(n-1)\sqrt{\pi d}}{\Gamma(d/2+1)} \right] + \gamma, \tag{B3}\]

where \( \lambda_i \) is the Euclidean distance of the \( i \)-th point to its nearest neighbour, \( \gamma = -\int_{0}^{\infty} e^{-z} \ln zdz \approx 0.57721 \) is the Euler–Mascheroni constant, and \( \Gamma(z) \) is the gamma function (Abramowitz & Stegun, 1965). It must be stated, however, that ‘reasonable’ estimation of differential entropy of non-renewal spiking activity usually requires large amounts of data, often not available in experimental recordings.

Appendix C: simulated spike trains

In this section we describe models of neuronal activity that were used to create Fig. 1 and that are not discussed in the main text. We employed the standard transformation method (Devroye, 1986) for generating the ISIs from known probability density functions.

- ad c. The spike train contains ISIs of two possible lengths, \( \theta_1 \) and \( \theta_2 \), distributed according to the Bernoulli distribution

\[
\text{Prob}(T = \theta_1) = 1 - \text{Prob}(T = \theta_2) = p. \tag{C1}\]

where \( p \in [0, 1] \). It holds

\[
E(T) = p \theta_1 + (1 - p) \theta_2, \tag{C2}\]

\[
C_V = \sqrt{(1 - p)p \theta_1 \theta_2} \cdot \frac{1}{\theta_1 - \theta_2}. \tag{C3}\]

From \( E(T) = 1 \), \( C_V = 1 \), and by choosing \( p = 1/10 \) follows \( \theta_1 = 4 \) s and \( \theta_2 = 2/3 \) s, which was used to generate the shown spike train.

- ad d. The probability density function of the Pareto distribution is

\[
f(t) = \begin{cases} 0, & t \in (0, b) \\ \frac{a^2}{b^a} t^{1-a}, & t \in [b, \infty) \end{cases} \tag{C4}\]

with parameters \( a > 2 \) and \( b > 0 \). The following relations hold: \( C_V = 1/\sqrt{a^2 - 2a} \) and \( E(T) = ab/(a - 1) \).

- ad e. The first-order Markov chain was generated by the Downton bivariate exponential model (Downton, 1970)

\[
f(t_1, t_2) = \frac{a^2}{1 - e} \exp \left( \frac{a}{e - 1} \right) I_0 \left( \frac{2a \sqrt{t_1 t_2}}{1 - e} \right). \tag{C5}\]

Where \( \rho \in (0, 1) \) is the first-order serial correlation, \( a = 1/\text{E}(T) \) and \( I_0(z) \) is the modified Bessel function of the first kind (Abramowitz & Stegun, 1965).

- ad f. Probability density function of the gamma distribution, parameterized by \( \mu = \text{E}(T) \) and \( C_V \) is

\[
f(t) = \left( \frac{1}{C_V \mu} \right)^{1/C_V} \Gamma(1/C_V) t^{1/C_V - 1} \exp \left( -\frac{t}{C_V \mu} \right). \tag{C6}\]

where \( \Gamma(z) \) is the gamma function.

- ad h. Probability density function of the inverse Gaussian distribution (Chihara & Folks, 1989), parameterized by \( \mu = \text{E}(T) \) and \( C_V \) is

\[
f(t) = \left( \frac{\mu}{2\pi C_V^2 t^3} \right)^{1/2} \exp \left[ -\frac{1}{2C_V^2 \mu} \left( \frac{t}{\mu} - \frac{\mu}{t} \right)^2 \right]. \tag{C7}\]
