### Abstract

High-resolution small-angle neutron scattering studies of the vortex lattice (VL) in  $\text{YNi}_2\text{B}_2\text{C}$  allow us to separate Bragg scattered intensities from the multi-domain VL that exists for  $B \parallel c$ . The first-order  $45^\circ$  reorientation of the VL at a field  $H_1$  is broadened by weak vortex pinning and characterised by a redistribution of domain populations between the low- and high-field vortex structures through the transition with no continuous distortion between the two phases. As nonlocal effects become weaker with increasing temperature,  $H_1(T)$  decreases while the field at which the VL becomes square,  $H_2(T)$ , increases. The nature of the high-field rhombic VL ( $H_1 < H < H_2$ ) close to  $H_{c2}(T)$  is discussed.

The lowest energy configuration for a repulsive array of magnetic-flux lines forming the vortex lattice (VL) is usually a two-dimensional (2D) hexagonal lattice, although the energy difference between hexagonal and square packing configurations is small ( $\approx 2\%$ ). In the tetragonal borocarbide materials  $[\text{RE}]\text{Ni}_2\text{B}_2\text{C}$  (RE = Lu, Y, Er, Tm, Ho, Dy) Fermi-surface anisotropy, combined with the relatively clean s-wave superconductivity results in significant nonlocal effects and a host of magnetic field, temperature and magnetic order dependent vortex lattice phases with either hexagonal, rhombic or square VL symmetry [1–3]. Meanwhile in the proposed p-wave and d-wave materials observation of a square VL provides strong evidence for these order parameter symmetries [4,5]. Several authors have been able to describe VL structures well below  $T_c$  using nonlocal corrections to the London model [6], or considering the effects of non-s-wave order parameter symmetries [7]. Close to  $T_c$  a Ginzburg–Landau approach

may be adopted coupling any Fermi surface or order parameter anisotropy via the addition of higher order terms in the GL expansion of the free energy [8].

SANS measurements were carried out using the D22 diffractometer, configured in a high-resolution mode, at the Institut Laue Langevin, Grenoble, France. The sample and electromagnet could be tilted together about a horizontal or vertical axis to satisfy the Bragg condition for any particular diffraction spot. Background measurements, taken with the sample in the normal state, have been subtracted from each pattern prior to analysis. The  $\text{YNi}_2\text{B}_2\text{C}$  crystal was grown with isotopic  $^{11}\text{B}$  to reduce neutron absorption.

Fig. 1(a) shows the diffraction image from the VL following field cooling in 100 mT to 4.5 K followed by a field oscillation of 10% the main field value (FCO). The FCO VL preparation technique effectively ‘shakes’ the VL from weak pinning sites in an attempt to achieve a vortex arrangement closer to equilibrium [3]. The positions of the twelve Bragg peaks do not lie on a circle of constant  $|q|$  expected for a VL with hexagonal symmetry. Rather, four intense Bragg reflections and two weaker peaks on either side correspond to two domains

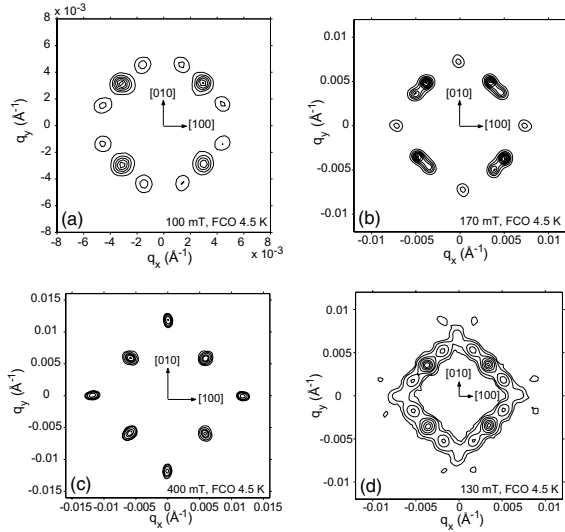

Fig. 1. SANS from the VL in  $\text{YNi}_2\text{B}_2\text{C}$  at 4.5 K for applied fields of (a) 100 mT, (b) 170 mT and (c) 400 mT. (d) Coexistence of low- and high-field VL phases at 130 mT.

of rhombic VL. By fitting 2D Gaussian functions to the multidetector data the VL opening angle,  $\beta$  ( $\simeq 54^\circ$ ), can be accurately determined. The integrated intensity of the weaker spots at a slightly larger  $|q|$  differ from the four strong spots by around 9%, consistent with the expected  $1/q^5$  reflectivity from the VL.

Fig. 1(b) shows the VL at 170 mT, above the field  $H_1$ , where the rhombic VL has reoriented by  $45^\circ$  and  $\beta$  ( $\simeq 82^\circ$ ) has abruptly switched to a value greater than  $60^\circ$ . Eight first-order Bragg peaks are present in pairs with each pair split azimuthally and the visible higher-order (1,1) reflections extended in the radial direction. With further increasing applied field  $\beta$  increases continuously until at a field  $H_2$   $\beta = 90^\circ$  and single domain square vortex lattice is observed (Fig. 1(c)).

The coexistence of both low- and high-field rhombic VL phases around the reorientation transition,  $H_1$ , is shown in Fig. 1(d) at 170 mT, 4.5 K, while Fig. 2 shows  $\beta$  over a wide field range from the low- to high-field rhombic phases until the lattice becomes square. High resolution SANS has allowed us to determine  $\beta$  accurately through the coexistence region. The vortex lattice structure does not appear to deform smoothly through  $H_1$  synonymous with a continuous reorientation transition. Instead,  $\beta$  takes well defined values corresponding to the VL phases above and below  $H_1$ . The inset to Fig. 2 shows the scattered intensity associated with the low- and high-field phases as a function of field through the coexistence regime, normalised by a  $q^5$  and  $B^2$  term to remove any  $q$  and field dependence of the reflected intensity from the VL. The broadened nature of the suggested first-order transition at  $H_1$  is due to weak static

disordering (pinning) of the VL. An entirely analogous behaviour is seen in the nonuniform melting of the VL in the high-temperature superconducting  $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$  [9] and consistent with general arguments pertaining to first-order transitions in the presence of weak disorder.

The nature of the temperature dependence of VL reorientation transitions at  $H_1$  and  $H_2$  is of ongoing study although general trends can be identified from the data presented in Fig. 2. The first-order reorientation transition,  $H_1(T)$ , decreases while the continuous transition to a square VL at  $H_2(T)$  increases with increasing temperature. Since nonlocal effects become weaker at higher temperatures (decreasing mean free path), Fig. 2 suggests that the phase diagram is dominated by the high-field rhombic vortex phase ( $H_1 < H < H_2$ ) at higher temperatures. A broadly similar behaviour is observed as a function of impurity doping in  $\text{LuNi}_2\text{B}_2\text{C}$  [10]. Incorporation of higher order terms into the GL expansion for the free energy predicts that the vortex lattice should be rhombic close to  $H_{c2}(T)$  for fields below  $H_2$  [8].  $H_2$  itself is expected to intercept  $H_{c2}(T)$  implying a square vortex lattice forms immediately upon high-field cooling ( $H > H_2$ ) through  $H_{c2}(T)$ , in contrast to Ref. [2] but in agreement with our ongoing high-resolution measurements.
